

Anaerobic glycolysis

Like most [tumors](#), [meningiomas](#) prefer anaerobic [glycolysis](#) for energy production ([Warburg effect](#)). This leads to an increased synthesis of the metabolite [methylglyoxal](#) (MGO). This [metabolite](#) is known to react with amino groups of [proteins](#). This reaction is called [glycation](#), thereby building advanced glycation endproducts (AGEs). In a study, Selke et al investigated the influence of glycation on two meningioma cell lines, representing the WHO grade I ([BEN-MEN-1](#)) and the WHO grade III ([IOMM-Lee](#)). Increasing MGO concentrations led to the formation of AGEs and decreased growth in both cell lines. When analyzing the influence of glycation on adhesion, chemotaxis and invasion, we could show that the glycation of meningioma cells resulted in increased invasive potential of the benign meningioma cell line, whereas the invasive potential of the malignant cell line was reduced. In addition, glycation increased the E-cadherin- and decreased the N-cadherin-expression in BEN-MEN-1 cells, but did not affect the [cadherin](#)-expression in IOMM-Lee cells ¹⁾.
