

# Anion gap level

Normal results are 3 to 10 mEq/L, although the normal level may vary from lab to lab. If your results are higher, it may mean that you have metabolic acidosis.

A total of 89 patients with intracerebral hemorrhage (ICH) were recruited. Of these, 68 and 21 patients were categorized into [screening cohort](#) and [validation cohorts](#), respectively. In the screening cohort, patients were categorized into three groups, according to the serum [anion gap levels](#) at [admission](#). Shen et al. dynamically recorded AG levels. Neurological and [cognitive functions](#) were assessed using the [Glasgow coma scale](#) (GCS), [Glasgow outcome scale](#) (GOS), and mini-mental state examination ([MMSE](#)) scale at different time points. Furthermore, in the validation cohort, 9 patients with increased AG levels underwent interventions to rectify the [electrolyte](#) imbalance.

In the screening cohort, statistical differences were observed for respiratory diseases ( $p=0.029$ ) among the three groups. The number of patients in the  $\geq 16$  mmol/L group (59.3%) was higher than that in the other groups. The mean scores of GCS in the  $\geq 16$  mmol/L group were lower than those in the other groups. The AG levels at admission had significant associations with 180-day GOS ( $p=0.043$ ) and 180-day MMSE ( $p=0.001$ ). Among them, the mean scores of the 180-day GOS and 180-day MMSE were lower in the  $\geq 16$  mmol/L group than in the other groups. In the validation cohort, AG intervention promoted recoveries of neurological and cognitive functions when compared to those without AG interventions.

[Anion gap level](#) is a potential predictive [biomarker](#) for the long-term outcomes of [spontaneous intracerebral hemorrhage](#) patients, and rectifying AG at [admission](#) improves the [spontaneous intracerebral hemorrhage prognosis](#) <sup>1)</sup>.
