Epidemiology

A cephalohematoma is noted in ~1%-2% of spontaneous vaginal deliveries and ~3%-4% of forceps or vacuum-assisted deliveries.

The most common location is under the right parietal bone and may be associated with an underlying skull fracture. Resolution typically occurs without treatment by 3-4 months of age. Anemia and hyperbilirubinemia are common sequelae, but cephalohematomas rarely become spontaneously infected.

In 2013 there was the first report describing a possible association between parvovirus B19 infection and cephalhematoma. Parvovirus B19 infection should be considered in the differential diagnosis of children who present with unexplained hemorrhage such as cephalhematoma or petechiae ¹⁾.

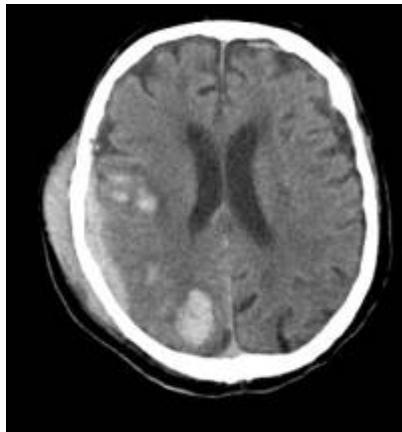

Classification

Subgaleal hematoma

Subperiosteal hematoma

see also Spontaneous subaponeurotic fluid collection

Diagnosis

Right frontotemporoparietal [intracranial acute epidural hematoma](#), up to 1 cm. thick, underlying a broad line of right temporoparietal Right parietal [subgaleal hematoma](#), up to 1cm. of thickness.

[Hemorrhage](#) under the [scalp](#)

Not to confuse with [subperiosteal hematoma](#).

Treatment

Surgical drainage of uncomplicated cephalohematomas is contraindicated because of the usually benign course, the propensity for reaccumulation with resultant hemodynamic instability, and the possibility of introducing microorganisms into a sterile space.

Complications

Anemia and hyperbilirubinemia.

[Calcified cephalhematoma](#)

Infection

Clinicians should be aware that cephalohematoma is a potential site of infection after fetal monitoring.

The incidence of associated system infection is high and may result in mortality. Appropriate diagnostic and therapeutic measures should be undertaken promptly if there are infectious signs ²⁾.

A 30-day-old infant presenting a E. coli meningitis with recurrence 5 days after stopping antibiotics. The clinical investigations concluded to the diagnosis of osteomyelitis of the parietal bone probably as a consequence of the infection of a cephalohematoma due to a wound caused by a foetal monitoring. Cephalohematoma is frequent in infant and is usually without consequences. Though rare, cases of infected cephalohematomas are described in the literature, with possible complications of meningitis (E. coli) and osteomyelitis. Sometimes the both pathologies are associated. A secondary infection of cephalohematomas must be taken in consideration when the etiology of a E. coli meningitis is not quite clear enough. In this situation, looking for an osteomyelitis whose presence may influence the

infant's treatment is needed. ³⁾.

Differential diagnosis

A **subgaleal hematoma** is an accumulation of blood within the loose **connective tissue** of the **subgaleal space**, which is located between the **galea aponeurotica** and the **periosteum**

Unlike a cephalohematoma, a **subgaleal hematoma** can be massive, leading to profound hypovolemic shock.

Case report

Age: 80 years

Gender: Female

Known **hypertension** (HTA).

History of **cholelithiasis**.

Valsartan/Hydrochlorothiazide tablets 160 mg/25 mg.

The patient was attended by **SAMU** due to **dizziness** and **presyncope** episode resulting in a **fall** with **traumatic brain injury** (TCE) and frontoparietal **Cephalohematoma**.

The patient received 300 mg of **amiodarone**. Additionally, the patient took Couldina (containing **ephedrine**) yesterday

COVID-19 vaccination: 3 doses, last administered in 2021.

No **Influenza vaccine** this year.

Vital Signs:

Blood Pressure: 180/80 mmHg

Heart Rate: 130 bpm

Oxygen Saturation: 98%

Conscious and oriented in all spheres with preserved **language**. General good condition, normal color, well-hydrated, well-perfused, and eupneic. Arrhythmic cardiac auscultation without audible murmurs or rubs. Respiratory examination with preserved vesicular murmur. Soft abdomen, non-tender, no signs of peritoneal irritation, no visceromegaly or masses. Negative Blumberg and Murphy signs. No edema or signs of deep vein thrombosis in lower extremities. No neurological focalities or neck stiffness. Left periorbital and temporal hematoma.

Elevated glucose, urea, and chloride levels. Elevated creatinine with reduced glomerular filtration rate. Elevated CRP, pro-BNP, troponin T, and ferritin.

Gasometry

Slightly acidic pH, normal pCO₂ and pO₂. Elevated lactate. Elevated prothrombin time (Quick index) and D-dimer.

Leukocytosis with increased neutrophils. Anemia with low red blood cell count. Elevated mean corpuscular volume (MCV). Coagulation

Normal APTT ratio, INR, and thrombin time. Elevated D-dimer.

Cerebral CT without contrast shows small frontal left subarachnoid hemorrhage and periventricular/subcortical white matter hypodensities suggestive of microvascular leukoencephalopathy.

Chest X-ray is unremarkable.

COVID Status:

Positive antigen test.

Management:

Metoprolol 5 mg IV initiated on arrival.

Recommended treatment for **atrial fibrillation**: **Eliquis** 5 mg every 12 hours indefinitely and Bisoprolol 2.5 mg daily.

Cardiology **appointment** requested for further evaluation before discharge.

Conclusion: The patient presented with a traumatic brain injury, subarachnoid hemorrhage, and **atrial fibrillation**. She has been admitted for observation, and the interdisciplinary team will manage her care. Follow-up with cardiology and neurosurgery is planned to address both the cardiac and neurological aspects of her condition.
