

Duret hemorrhage

Duret hemorrhage is a small haemorrhage (or multiple haemorrhages) seen in the [medulla](#) or [pons](#) of patients who are rapidly herniating.

Raised intracranial pressure causes the [brainstem](#) and mesial temporal lobes to be forced downwards through the tentorial hiatus. As a result of this shift, it is believed that perforating branches from the basilar artery and/or draining veins are damaged with resultant parenchymal haemorrhage. Usually it is seen in patients with severe herniation for 12-24 hours prior to death ^{[1\)](#)}.

Bermúdez et al. report a case of Duret haemorrhage with full recovery ^{[2\)](#)}.
